Abstract

Experiments on chalcogenide glasses show that local elasticity as measured by Raman scattering and the kinetic heat-flow near T_g as established from temperature modulated differential scanning calorimetry each display a threshold behavior associated with network connectivity as defined by the mean coordination, $\langle r \rangle$, near $\langle r \rangle = \langle r \rangle_c \simeq 2.40$. Network plasticity of amorphous group IV networks as deduced from nanometer-indentation hardness measurements varies linearly with $\langle r \rangle$ once $\langle r \rangle > 2.40$. Consequences of these results connecting physical behavior of covalent networks with their connectivity are discussed. © 1997 Elsevier Science B.V.

1. Introduction

One of the success stories in glass science is the correlation in covalently bonded networks between a variety of physical properties and network connectivity as defined by the mean coordination number $\langle r \rangle$. In Table 1 we summarize experimental results and numerical simulations that bear on this correlation [1–19]. These observations underscore the central role of nearest-neighbor valence force fields as effective constraints [20] in determining the physical behavior of covalent network glasses. In this work we shall discuss some recent results from several techniques, namely, Raman scattering, temperature modulated differential scanning calorimetry, and nanometer-indentation hardness measurements that show the above mentioned correlation in a rather striking fashion and provide additional insights.

2. Constraint theory, random network simulations, local elasticity and Raman scattering

2.1. Constraint theory and random network simulations

A covalently bonded random network progressively stiffens as its connectivity or mean coordination number, $\langle r \rangle$, increases. Networks consist-
